Acknowledgements

Our thanks go to our entire research team who confirmed this medical breakthrough with ingenuity and perseverance. First and foremost we owe our appreciation to Dr. Waheed Romi, the head of our cancer research department who conducted and supervised these important experiments for more than a decade. We also thank Dr. Shrirang Netke, Dr. Vadim Ivanov, Dr. Raxit Jariwalla, Nusrath Roomi and Tatiana Kalinovsky for promoting this breakthrough research.

Our thanks go to Lisa Smith for assistance in the layout of this book as well as Cathy Flowers and John Journey for reading corrections.

We are grateful to Betsy Long, Earle Hall, Christian Kammler and Thomas Wenn, and Paul Anthony Taylor for organisational support.

We also wish to express our gratitude to all members of our international legal team that has worked for more than a decade to protect this breakthrough against the legal attacks of the status quo lobby.

We thank Werner Pilniok, Baerbel Saliger and all other patients who had the courage to publicly tell their life story.

We pay special reference to those patients, young and old, who failed in their efforts to fight the disease and who may have had a chance had they not lost so much time in the deadlocks of conventional medicine.

We are especially grateful to August Kowalczyk, Jerzy Ulatowski and other survivors of the Auschwitz concentration camp. They remain a lasting inspiration to us and our work. We are united with them in the commitment: ‘Never again!’

Particular thanks go to the thousands of members of our international Health Alliance who have supported our research for more than a decade. Without you this breakthrough would not have been possible.

We thank our families for their support and patience.

We also thank Andy and Jamie Kerr for an inspirational environment when we wrote this book.

Finally, our thanks go to all those who have remained an invaluable source of motivation to us through their scepticism and opposition.
The following scientific publication from 1992 laid the conceptual foundation for our research in cancer. It was written by Dr. Rath and supported by Nobel Laureate Linus Pauling.

**Plasmin-Induced Proteolysis and the Role of Apoprotein(a), Lysine, and Synthetic Lysine Analogos**

M. Rath, L. Pauling

**Summary**

Most human diseases, independent of their individual genetic or exogenous origin, proliferate via similar pathomechanisms. One of these universal pathways is propagated by oxygen free radicals. Here we present another universal pathomechanism: the degradation of the connective tissue by the protease plasmin. This mechanism had been described for some diseases but its universal character has still been insufficiently understood. We propose now that the proliferation of cancer, cardiovascular disease (CVD), and also inflammatory and many other diseases depends to a varying degree on this pathomechanism. Activated macrophages, but also cancer cells, virally transformed cells, and other pathogenic cells secrete considerable amounts of plasminogen activators, which lead to an activation of plasminogen to the protease plasmin which activates procollagenase to collagenase. The resulting degradation of the extracellular matrix is a precondition for the proliferation and the clinical manifestation of any disease. Most acute and chronic diseases make use of this pathomechanism. This pathomechanism is the exacerbation of a mechanism used under physiological conditions by a variety of cellular systems of the human body. The exacerbation under pathological conditions is the result of a chronic imbalance between activators and inhibitors of this pathway. Apoprotein(a), apo(a), by virtue of its homology to plasminogen is proposed to be a competitive endogenous inhibitor of plasmin induced proteolysis and tissue degradation. The essential amino acid L-lysine functions as an exogenous inhibitor of this pathway. Therapeutic administration of L-lysine and synthetic lysine analogs, such as tranexamic acid, should lead to an effective control of plasmin-induced tissue degradation. Comprehensive clinical confirmation of this work will particularly improve the therapeutic options for advanced forms of CVD, cancer, and inflammatory and infectious diseases, including AIDS.

**Introduction**

In recent years the international research community became fascinated by a unique protein in the human body: apoprotein(a) [apo(a)]. In the three decades since its discovery apo(a) has been primarily discussed in relation to its deleterious effects on human health, in particular on cardiovascular disease (CVD). We did not accept that apo(a) should have only disadvantageous properties. According to the laws of evolution apo(a) must have beneficial properties that by far outweigh its disadvantages. Consequently, we discovered that under physiological conditions apo(a) functions as an adhesive protein, mediating organ differentiation and growth. Under pathophysiological conditions apo(a) primarily substitutes for ascorbate deficiency and increases tissue stability by compensating for impaired collagen metabolism, and by promoting tissue repair (1). Moreover, we proposed that apo(a) functions as an inhibitor of important pathomechanisms involved in the proliferation of many diseases. These pathomechanisms are favored during ascorbate deficiency. One of these universal pathomechanisms is the damaging effect of oxygen free radicals, which is attenuated by the antioxidative function of apo(a) as a proteinthiol (2).

Apo(a) also led us to determine the universal importance of another pathomechanism: the enzymatic degradation of the connective tissue by the protease plasmin. We recently proposed that apo(a), by virtue of its homology to plasminogen, functions as a competitive inhibitor of plasmin-induced proteolysis (3). In this publication we describe the universal character of this mechanism and the role of apo(a) in more detail. Plasmin-induced proteolysis had been described as a pathomechanism for some diseases, e.g. cancer and certain viral diseases (4,5). In cardiovascular disease, however, this mechanism has received little, if any, attention. The insufficient understanding of the universal character of this pathomechanism is the exacerbation of a mechanism used under physiological conditions by a variety of cellular systems of the human body. The exacerbation under pathological conditions is the result of a chronic imbalance between activators and inhibitors of this pathway. Apoprotein(a), apo(a), by virtue of its homology to plasminogen is proposed to be a competitive endogenous inhibitor of plasmin induced proteolysis and tissue degradation. The essential amino acid L-lysine functions as an exogenous inhibitor of this pathway. Therapeutic administration of L-lysine and synthetic lysine analogs, such as tranexamic acid, should lead to an effective control of plasmin-induced tissue degradation. Comprehensive clinical confirmation of this work will particularly improve the therapeutic options for advanced forms of CVD, cancer, and inflammatory and infectious diseases, including AIDS.
Plasmin-Induced Proteolysis Under Physiological Conditions

Plasmin-induced proteolysis is a physiological mechanism that occurs ubiquitously in the human body. The main cellular defense systems, monocytes, macrophages, and neutrophiles, use this mechanism for their migration through the body compartments. They secrete plasminogen activators, which then activate plasminogen to plasmin. This mechanism makes efficient use of high blood and tissue concentrations of the proenzyme, plasminogen, which represents a huge reservoir of potential proteolytic activity. The activated protease plasmin then converts procollagenases into collagenases (6), and quite possibly also activates other enzymes, leading to a local degradation of the connective tissue. This local degradation of the connective tissue paves the way for the migration of macrophages through the body. The proteolytic effect of plasmin is also involved in increasing vascular permeability (7). This effect facilitates the infiltration of monocytes and other blood cells from the circulation to the tissue sites of increased requirement. Physiological conditions in which plasmin-induced proteolysis occurs include different forms of tissue formation and reorganization such as neurogenesis, vascularization, and, quite probably, growth.

Of particular importance is plasmin-induced proteolysis during the remodeling of female reproductive organs. Under hormonal stimulation mammary and uterine cells secrete plasminogen activator and thereby initiate the morphologic changes of the organ during pregnancy and lactation (4). A particularly striking example for the effectiveness of this mechanism is ovulation. Luteinizing hormone (LH) and follicle cell stimulating hormone (FSH) stimulate the secretion of plasminogen activators from granulosa cells (8). The subsequent degradation of the ovarian connective tissue is a precondition for ovulation (Figure 1a). Similarly trophoblast cells use plasmin-induced proteolysis to invade the wall of the uterus during embryo implantation in early pregnancy. In all these conditions enzyme production is transient and is precisely regulated by hormones and other control mechanisms.

Plasmin-Induced Proteolysis Under Physiological Conditions

Plasmin-induced tissue degradation contributes to the proliferation of most diseases. Of particular interest is the fact that similar mechanisms are induced by attacking pathogens as they are used by the defending host cells, e.g. macrophages. In many pathological conditions macrophages become ‘activated’. This activation reflects a particular state of alert that is characterized by an abundant release of secretory products. These products include oxygen metabolites, collagenases, elastases, and a significantly increased secretion of plasminogen activators. It is immediately obvious that this mechanism needs to be precisely controlled. Therefore macrophages also secrete inhibitory products including plasmin inhibitors and a2-macroglobulin which are able to inactivate plasmin and many other proteases. Any imbalance in this control system leads to an exacerbation of this mechanism and to continued tissue degradation. Chronic activation of macrophages and an exertion of the control mechanisms eventually lead to a sustained degradation of the connective tissue and to an accelerated proliferation of the disease. It is, therefore, not unreasonable for us to propose that plasmin-induced tissue degradation contributes, to a varying degree, to the proliferation of all diseases.

This mechanism is, however, not limited to macrophages and other defense cells of the human body. In the following sections we shall discuss this pathomechanism for the most important diseases in more detail.

Cancer

Malignant transformation of many cells of the human body leads to an uncontrolled secretion of plasminogen activators. In this situation the secretion of plasminogen activators is not a temporary event, but is rather a characteristic feature of malignant cells. The magnitude of increase in plasminogen-activator production, between 10 and 100 fold, renders this enzyme unique among the biochemical changes associated with oncogenic transformation. Moreover, plasminogen-activator secretion occurs independently of the induction mechanism and can be found as the result of oncogenic viruses or chemical carcinogens. Most importantly, the amount of plasminogen activators secreted was, in general, associated with the degree of malignancy (4,5). Immunohistological studies showed that the concentration of plasminogen activators in the vicinity of a tumor is highest at the sites of its invasive growth (9).

Because of the prominent role of plasmin-induced proteolysis in female reproductive organs under physiological conditions it is no surprise that the exacerbation of this mechanism is particularly frequent in malignancies of the female reproductive organs. Cancer cells of the breast, the uterus, the ovaries, and other organs continuously secrete increased amounts of plasminogen activators, destroy the surrounding extracellular...
They become macrophages. Their activation inside the vascular wall is enhanced by oxidatively modified lipoproteins and other challenging mechanisms (3,10). Once they are activated a similar cascade of events occurs, as in any other disease: increased secretion of plasminogen activators, activation of procollagenases by the protease plasmin, and degradation of the connective tissue in the vascular wall. Simultaneously, plasmin increases the permeability of the vascular wall, leading to a further increase in the infiltration of plasma constituents. The perpetuation of these pathomechanisms leads to the development of atherosclerotic lesions. This mechanism is particularly effective when the vascular wall is already destabilized by a deficiency in ascorbate. As described recently in detail (3), this instability is primarily unmasked at sites of altered hemodynamic conditions, such as the branching regions of the coronary arteries. It is therefore no surprise that increased amounts of plasminogen activators were detected in these branching regions of human arteries. Moreover, atherosclerotic lesions in general were found to contain significantly higher amounts of plasminogen activators than grossly normal arterial wall (11). It is a remarkable fact that these early observations have not been followed up systematically. This negligence suggests that the universal character of uncontrolled plasmin-induced proteolysis for disease proliferation has not yet been fully understood. It is the aim of this paper to close this gap.

Apoprotein(a) - An Inhibitor of Plasmin-Induced Proteolysis

In identifying the universal importance of plasmin-induced proteolysis for most diseases we were once again guided by apo(a) and its increased demand as reflected by the elevated plasma concentrations in many pathological conditions. As discussed above, apo(a) exerts a multitude of functions under physiological and pathophysiological conditions. Here we focus on the role of apo(a) as an endogenous competitive inhibitor of plasmin-induced proteolysis and tissue degradation.

Apo(a) is a glycoprotein with a unique structure. It is essentially composed of a repetitive sequence of the kringle structures highly homologous to the kringle IV of the plasminogen molecule. The gene for apo(a) is located in the direct vicinity of the plasminogen gene on chromosome 6. It has been proposed that the apo(a) molecule derives from the plasminogen molecule or that the two genes share a common ancestral gene (12). As of today no explanation has been offered as to why among all five kringles of plasminogen it is almost exclusively kringle IV that was chosen by nature to compose the apo(a) molecule. We do not accept this selective advan-
tage of kringle IV as a coincidence. We propose that at least one of the reasons for the repetition of kringle IV in apo(a) is closely related to the structure/function of kringle IV in the plasminogen molecule.

It is not unreasonable for us to propose that apo(a), by virtue of its multiple kringle IV structures, is a competitive inhibitor of plasmin-induced proteolysis. Apo(a) could be involved in the control of this pathway without interfering with critical functions of plasminogen mediated by other kringles of the plasminogen molecule. Consequently, the more kringle IV repeats one apo(a) molecule contains, the more effective this apo(a) isoform would be as an inhibitor. This concept could not only explain the selective advantage of kringle IV versus the other kringle structures, but it could also explain the great variation in genetically determined plasma Lp(a) concentrations, which largely reflect the inverse relation between the number of intramolecular kringle IV repeats and the synthesis rate of apo(a) molecules.

Supportive evidence for a role of apo(a) in the control of plasmin-induced proteolysis is also provided by a number of observations. Apo(a) has been shown to attenuate tissue-plasminogen-activator-induced fibrinolysis and competitively interfere with plasminogen- and plasmin-induced pathways (review in 14). Moreover, immunohistological studies in various diseases showed a preferential deposition of apo(a) at the site of increased demand for a control of plasmin-induced proteolysis. In several hundred vascular specimens representing various degrees of cardiovascular disease apo(a) was found primarily to be located in the subendothelium, quite possibly counteracting the increased endothelial permeability. In advanced atherosclerotic lesions apo(a) was preferentially found around the lesion core, particularly at the edges of the lesion (15), the main sites of chronic repair processes. In a comprehensive morphological study in different forms of cancer apo(a) was found to be deposited in the vicinity of the cancer process (Dr. A. Niendorf, personal communication). Both studies were conducted with the same monoclonal antibodies not cross-reacting with plasminogen. A preliminary report is also available for the deposition of apo(a) in the microvasculature of inflammatory processes (16). We predict that apo(a) will also be found to play an important role in the containment of infectious diseases, including AIDS. The role of apo(a) as a competitive inhibitor of plasmin-induced proteolysis is not limited to pathological conditions. An increased demand of apo(a) was also observed during the period of uterus transformation in early pregnancy (17).

In summary, apo(a) is suggested to be an important element in the endogenous control system of plasmin-induced proteolysis. Apo(a) may back-up antiplasmin and other endogenous inhibitors of this pathway particularly during chronic activation of this mechanism. Beside endogenous inhibitors of plasmin-induced tissue degradation there are also exogenous inhibitors. The universal importance of the pathomechanism described here immediately suggests the great value of these exogenous inhibitors in the therapy of many diseases.

The Therapeutic Use of Lysine and Synthetic Lysine Analogs

Lysine, an essential amino acid, is the most important naturally-occurring inhibitor of this pathway. As opposed to the competitive inhibition by apo(a), lysine inhibits plasmin-induced proteolysis in a direct way. Lysine attenuates an overshooting activation of plasmin, at least in part, by occupying the lysine binding sites in the plasminogen molecule. Since lysine is an essential amino acid, its availability is not regulated endogenously. Insufficient dietary lysine intake invariably leads to a deficiency of this amino acid and thereby weakens the natural defense against this pathomechanism. Moreover, chronic activation of plasminogen by cancer cells, virally transformed cells, or macrophages leads to an additional relative lysine deficiency and thereby to an acceleration of the underlying disease. The therapeutic value of lysine has been documented for a variety of diseases, including viral diseases (18), and recently in combination with ascorbate for cardiovascular disease (19).

Synthetic lysine analogs such as epsilon-aminocaproic acid, paraamino-methylbenzoic acid and trans-aminocyclohexanoic acid (tranexamic acid) are potent inhibitors of plasmin-induced proteolysis. These substances, in particular tranexamic acid, have been successfully used in the treatment of a variety of pathological conditions, such as angiohematoma, colitis ulcerosa, and others. Most remarkable results were reported from the treatment of patients with late-stage cancer of the breast (20) and the ovaries (21) and also for cancer of other origins (22). We have recently suggested the therapeutic use of synthetic lysine analogs for the reduction of atherosclerotic plaques (3).

On the basis of the work presented here, comprehensive clinical studies should be initiated to establish the critical role of lysine in the prevention and treatment of various diseases without delay. A daily intake of 5 grams
of lysine and more (19,23) has been described to be without side effects. On the basis of the encouraging therapeutic results with tranexamic acid, particularly in inhibiting and reducing late-stage cancer, these substances should now be extensively tested for a broad introduction into clinical therapy, particularly for advanced forms of cancer, CVD, and AIDS. A possible explanation of why this has not happened long ago may be the argument that these substances may induce coagulative complications. They are, however, protease inhibitors and inhibit not only fibrinolysis but also coagulation (24). Moreover, tranexamic acid has been given for more than 10 years without clinical complications (25). We have proposed that the risk of any hemostatic complication will be further reduced by a combination of these compounds with ascorbate and other vitamins with anticoagulative properties (3). This medical consideration is, however, not the only factor why these compounds are not used much more frequently and why thousands of patients are still deprived of optimum therapy. There is also an economic factor. Patent protection is a guiding principle of any pharmaceutical company in developing or marketing a drug. Lysine, like many other nutrients, is not patentable and the patents for the clinically approved synthetic lysine analogs, including tranexamic acid, have expired. The negligence of these substances may be explainable from the economic point of view; from the perspective of human health there is no justification for this delay.

Conclusion

Here we have described plasmin-induced proteolysis as a universal pathomechanism propagating cancer, and cardiovascular, inflammatory, and many other diseases. Plasmin-induced tissue degradation under pathological conditions is an exacerbation of a physiological mechanism. Apo(a) is suggested to function as a competitive endogenous inhibitor of this pathway. On the basis of the selective advantage of apo(a) in the evolution of man it comes as no surprise that apo(a) should lead us on the way to recognize the universal importance of this pathomechanism. Further clinical confirmation of the therapeutic value of lysine and its synthetic analogs may provide new options for an effective therapy for millions of people. We predict that the use of lysine and synthetic lysine analogs, particularly in combination with ascorbate, will lead to a breakthrough in the control of many forms of cancer and infectious diseases, including AIDS, as well as many other diseases.
